Abstract

Technological advances make the distinction between artificial (e.g., computer-generated 25 faces) and real stimuli increasingly difficult, and the factors that drive our beliefs regarding the nature of ambiguous stimuli remain largely unknown. In this study, 150 participants 27 rated 109 pictures of faces on 4 characteristics (attractiveness, beauty, trustworthiness, familiarity). The stimuli were then presented again with the new information that a 29 number of them were AI-generated, and participants had to rate each image according to 30 whether they believed them to be real or fake. Strikingly, despite all images being pictures 31 of real faces from the same database, most participants rated a large portion of them as "fake". Moreover, our results suggest a gender-dependent role of attractiveness on reality 33 judgements, with faces rated as more attractive being classified as more real. We also report links between reality beliefs tendencies and dispositional traits such as narcissism 35 and paranoid ideation.

37 Keywords: attractiveness, simulation monitoring, fiction, deep fakes, sense of reality

Too Beautiful to be Fake: Attractive Faces are Less Likely to be Judged as Artificially Generated

For the first time in human history, technology has enabled the creation of
near-perfect simulations indistinguishable from reality. These artificial, yet realistic
constructs permeate all areas of life through immersive works of fiction, deep fakes (real-like
images and videos generated by deep learning algorithms), virtual and augmented reality
(VR and AR), artificial beings (artificial intelligence "bots" with or without a physical
form), fake news and skewed narratives, of which ground truth is often hard to access
(Nightingale & Farid, 2022). Such developments not only carry important consequences for
the technological and entertainment sectors, but also for security and politics - for instance
if used for propaganda and disinformation, recruitment into malevolent organizations, or
religious indoctrination (Pantserev, 2020). This issue is central to what has been coined
the "post-truth era" (Lewandowsky et al., 2017), in which the distinction (and lack
thereof) between authentic and simulated objects will play a critical role.

While not all simulations have achieved perfect realism (e.g., Computer Generated Images - CGI in movies often lack certain key details that makes them visually distinct from real images, McDonnell & Breidt, 2010), it is fair to assume that these technical limitations will become negligible in the near future, particularly in the field of face generation (Moshel et al., 2022; Nightingale & Farid, 2022; Tucciarelli et al., 2020). Such performance, however, leads to a new question: if real and fake stimuli cannot be distinguished based on their objective characteristics, how can we make judgements regarding their nature?

Literature shows that the context surrounding a stimulus often plays an important role in the assessment of its reality (a process henceforth referred to as *simulation* monitoring, Makowski, 2018; Makowski, Sperduti, et al., 2019). With the extensive search and processing of cues within ambiguous stimuli being an increasingly complex and

cognitively effortful strategy (Michael & Sanson, 2021; Susmann et al., 2021), people tend to draw on peripheral contextual cues (**Figure 1**), such as the source of the stimulus (e.g., in what journal has information been published), and its credibility, authority and expertise, to help facilitate their evaluation (Michael & Sanson, 2021; Petty & Cacioppo, 1986; Susmann et al., 2021). However, the automization and decontextualization of information allowed by online social media (where text snippets or video excerpts are mass-shared with little context) makes this task increasingly difficult (Berghel, 2018; Y. Chen et al., 2015). Thus, in the absence of clear contextual information, what drives our beliefs of reality?

Evidence suggests that inter-individual characteristics play a crucial role in simulation monitoring, with factors such as cognitive style, prior beliefs, and personality 75 traits (Bryanov & Vziatysheva, 2021; Ecker et al., 2022; Sindermann et al., 2020). For 76 instance, individuals with stronger analytical reasoning have been found to better 77 discriminate real from fake stimuli (Pehlivanoglu et al., 2021; Pennycook & Rand, 2019), and prior knowledge or beliefs about the stimulus influences one's perception of it by 79 biasing the attention deployment towards information that is in line with one's expectations (Britt et al., 2019). Furthermore, dispositional traits, such as high levels of 81 narcissism and low levels of openness and conscientiousness, have been associated with 82 greater susceptibility to fake news (Piksa et al., 2022; Sindermann et al., 2020).

Beyond stimulus- and individual-related characteristics, evidence suggests that the interaction between the two (i.e., the subjective reaction associated with the experience of a given stimulus), contributes to simulation monitoring decisions. For instance, the intensity of experienced emotions have been shown to increase one's sense of presence - the extent to which one feels like "being there", as if the object of experience was real - when engaged in a fictional movie or a VR environment (Makowski et al., 2017; Sanchez-Vives & Slater, 2005). Conversely, beliefs that emotional stimuli were fake (e.g., that emotional

Determinants of Simulation Monitoring

« Is this information real or fake? »

« Real » = genuine, authentic « Fake » = artifical, simulated, deceptive

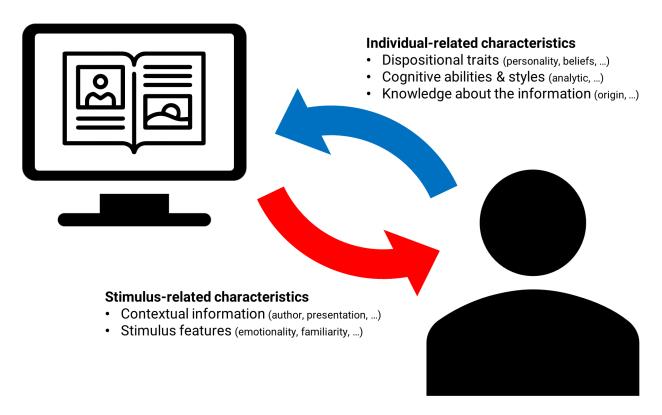

Figure 1. The decision to believe that an ambiguous stimulus (of any form, e.g., images, text, videos, environments, ...) is real or fake depends of individual characteristics (e.g., personality and cognitive styles), stimulus-related features (context, emotionality), and their interaction, which can manifest for instance in our bodily reaction.

- scenes were not authentic but instead involved actors and movie makeup) were found to
- result in emotion down-regulation (Makowski, Sperduti, et al., 2019; Sperduti et al., 2017).
- In line with these findings, studies on susceptibility to fake news have also found
- heightened stimulus emotionality to be associated with greater belief (Bago et al., 2022;
- Martel et al., 2020). Additionally, other factors, such as the stimuli's perceived
- self-relevance (Goldstein, 2009; Sperduti et al., 2016), as well as familiarity (Begg et al.,
- 97 1992), could also play a role in guiding our appraisal of a stimulus.
 - AI-generated images of faces, due to their popularity as a target of CGI technology

and to the possibility of experimentally manipulating facial features, are increasingly used to study face processing in relationship with saliency or emotions, as well as to other 100 important components of face evaluation, such as trustworthiness or attractiveness (Balas 101 & Pacella, 2017; Calbi et al., 2017; Sobieraj & Krämer, 2014; Tsikandilakis et al., 2019). 102 Interestingly, artificially created faces rated as more attractive (by an independent group of 103 raters) were perceived as less real (Tucciarelli et al., 2020). Conversely, Liefooghe et al. 104 (2022) reports that attractiveness ratings were significantly lower when participants who 105 were told that the faces were AI-generated were compared to those who had no prior 106 knowledge. Whereas this line of evidence suggests that reality beliefs have an effect on face 107 attractiveness ratings, the opposite question - whether attractiveness could drive 108 simulation monitoring - has received little attention to date. 109

This study primarily aims at exploring the effect of facial attractiveness on simulation 110 monitoring, i.e., on the beliefs that an image is real or artificially generated. Based on the 111 embodied reality theory (outlined in Makowski, 2018; Makowski, Sperduti, et al., 2019), 112 which suggests that salient and emotional stimuli are perceived to be more real, we 113 hypothesize a quadratic relationship between perceived realness and attractiveness: faces 114 rated as highly attractive or unattractive will more likely be believed to be real. We expect 115 a similar relationship with trustworthiness ratings given its well-established link with 116 attractiveness (Bartosik et al., 2021; Garrido & Prada, 2017; Liefooghe et al., 2022; Little 117 et al., 2011), and a positive relationship with familiarity (as more familiar faces would appear as more salient, self-relevant and anchored in reality). Additionally, we will further 119 explore the link shared by dispositional traits, such as personality and attitude towards AI, with simulation monitoring tendencies. This study aims beyond the investigation of the 121 discriminative accuracy between "true" photos and "true" artificially-generated images, 122 focusing on the beliefs that a stimulus is real or fake, independently of its true nature.

Methods

125

experiment code, raw data, analysis script with complementary figures and analyses, 126 preregistration, etc.) is available at https://github.com/RealityBending/FakeFace. 127 **Procedure.** In the first part of the study, participants answered a series of 128 personality questionnaires, including the Mini-IPIP6 (24 items, Sibley et al., 2011) 129 measuring 6 personality traits, the SIAS-6 and the SPS-6 (6 items each, Peters et al., 130 2012) assessing social anxiety levels, the FFNI-BF (30 items, Jauk et al., 2022) measuring 131 9 facets of narcissism; the R-GPTS (18 items, Freeman et al., 2021) measuring 2 132 dimensions related to paranoid thinking; and the IUS-12 (12 items, Carleton et al., 2007) 133 measuring intolerance to uncertainty. Self-rated attractiveness was also assessed using 2 134 items - one measuring general attractiveness ("How attractive would you say you are?", 135 Marcinkowska et al. (2021)) and the other measuring physical attractiveness ("How would 136 you rate your own physical attractiveness relative to the average", Spielmann et al. 137 (2020)). Finally, we devised 5 items pertaining to expectations about AI-generated image 138 technology ("I think current Artificial Intelligence algorithms can generate very realistic 139 images"). To lower their saliency and the possibility of it priming the subjects about the task, we mixed these items with 5 items from the general attitudes towards AI scale (GAAIS, Schepman & Rodway, 2020). This scale was presented after the social anxiety questionnaires. 3 attention check questions were also embedded in the surveys.

In line with open-science standards, all the material (stimuli generation code,

In the second part of this study, 109 images of neutral-expression faces from the validated American Multiracial Face Database (AMFD, (J. M. Chen et al., 2021)) were presented to the participants for 500ms each, in a randomized order, following a fixation cross display (750 ms). After each stimulus presentation, ratings of *Trustworthiness* ("I find this person trustworthy") and *Familiarity* ("This person reminds me of someone I know") were collected using visual analog scales. Notably, as facial attractiveness is a

multidimensional construct, encompassing evolutionary, sociocultural, biological as well as cognitive aspects (Han et al., 2018; Rhodes et al., 2006), we assessed attractiveness using 2 visual analog scales, measuring general *Attractiveness* ("I find this person attractive") and physical *Beauty* ("This face is good-looking").

In the last part of the study, participants were informed that "about half" of the images previously seen were AI-generated (the instructions used a cover story explaining that the aim of the research was to validate a new face generation algorithm). The same set of stimuli was displayed again for 500 ms in a new randomized order. This time, after each display, participants were asked to express their belief regarding the nature of the stimulus using a visual analog scale (with *Fake* and *Real* as the two extremes). The study was implemented using *jsPsych* (De Leeuw, 2015), and the exact instructions are available in the experiment code.

Participants. One hundred and fifty participants were recruited via *Prolific*, a crowd-sourcing platform recognized for providing high quality data (Peer et al., 2022). The only inclusion criterion was a fluent proficiency in English to ensure that the experiment instructions would be well-understood. Participants were incentivised with a reward of about £7.5 for completing the study, which took about 45 minutes to finish. Demographic variables (age, gender, sexual orientation, education and ethnicity) were self-reported on a voluntary basis.

We excluded 5 participants that either failed 2 (>= 66%) or more attention check questions, took an implausibly short time to finish the questionnaires or had incomplete responses. The final sample included 145 participants (Mean age = 28.3, SD = 9.0, range: [19, 66]; Sex: 48.3% females, 51.0% males, 0.7% others).

Data Analysis. The real-fake ratings (measured originally on a [-1, 1] analog scale)
were converted into two scores, corresponding to two conceptually distinct mechanisms:
the dichotomous *belief* (real or fake, based on the sign of the rating) and the *confidence*

(the rating's absolute value) associated with that belief. The former was analyzed using logistic mixed models, which modelled the probability of assigning a face to the real (>= 0) as opposed to fake (< 0). The latter, as well as the other face ratings (attractiveness, beauty, trustworthiness and familiarity), was modelled using mixed beta regressions (suited for outcome variables expressed in percentages). The models included the participants and stimuli as random factors.

We started by investigating the effect of the procedure and instructions to check
whether the stimuli (which were all images of real faces) were judged as fake in sufficient
proportion to warrant their analysis. Additionally, we assessed the effect of the re-exposure
delay, i.e., the time between the first presentation of the image (corresponding to the face
ratings) and the second presentation (for the real-fake rating).

The determinants of reality beliefs were modelled separately for attractiveness, 187 beauty, trustworthiness, and familiarity, using second order raw polynomials coefficients to 188 allow for possible quadratic relationships (Figure 2). Aside from attractiveness 189 (conceptualized as a general construct), models for beauty, trustworthiness and familiarity 190 were adjusted for the two remaining variables mutatis mutandis. We took into account 191 the gender of participants and stimuli by retaining the stimuli that were aligned with the 192 participants' sexual preference (e.g., female faces for homosexual females, male faces for 193 heterosexual females, and both for bisexual participants), and modeling the interaction 194 with the participants' gender. For the attractiveness and beauty models, we then added 195 the interaction with the reported self-attractiveness (the average of the two questions 196 pertaining to it) to investigate its potential modulatory effect. Finally, we investigated the 197 inter-individual correlates of simulation monitoring with similar models (but this time, for 198 all items regardless of the participant's gender or sexual orientation) for each questionnaire, 199 with all of the subscales as orthogonal predictors. 200

The analysis was carried out using R 4.2 (R Core Team, 2022), the tidyverse

201

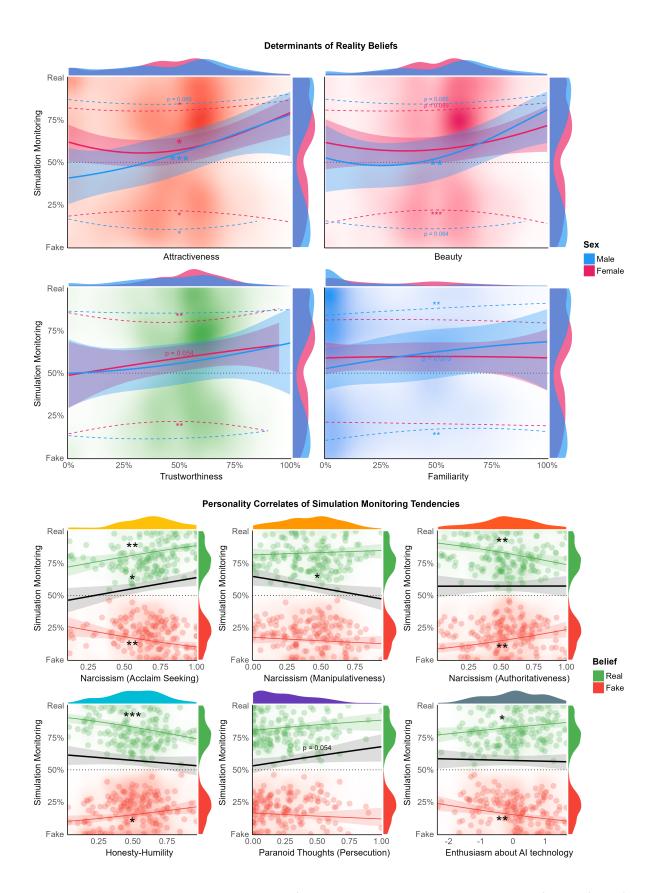

Figure 2. Top part shows the effect of face ratings on 1) the probability of judging a face as real vs. fake (solid line) and 2) on the confidence associated with that judgement (dashed lines) depending on the sex. Bottom part shows the effect of personality traits on the belief (black line) and the confidence associated with it (colored lines). The points are the average per participant confidence for both types of judgements. Stars indicate significance (p < .001***, p < .01**, p < .05*)

Wickham et al., 2019), and the *easystats* collection of packages (Lüdecke et al., 2021, 2019, 2020; Makowski et al., 2020; Makowski, Ben-Shachar, et al., 2019). As all the details, scripts and complimentary analyses are open-access, we will focus in the manuscript on findings that are highly statistically significant (p < .01).

206 Results

Manipulation Check. Only one image file yielded a strong simulation monitoring 207 bias (> 85%), being classified as fake by 88.7% of participants. This image was removed 208 from further analysis, leaving 108 trials per participant. On average, across participants, 209 44% of images (95%~CI [0.12, 0.64]) were judged as fake and 56% of images (95%~CI [0.36, 210 0.84) as real. An intercept-only model with the participants and images as random factors 211 showed that the Intraclass Correlation Coefficient (ICC), which can be interpreted as the 212 proportion of variance explained by the random factors, was of 9.0% for the participants 213 and 9.6% for the stimuli. 214

While the delay of stimulus re-exposure stimulus did not have a significant effect on participants' beliefs of reality ($OR=1.00,\,95\%$ CI=[0.99,1.00]), judgement confidence was found to be negatively associated with re-exposure delay when the faces were judged as real ($\beta=-0.006,\,95\%$ $CI=[-0.1,0.002],\,p=.004$)

Determinants of Simulation Monitoring. Attractiveness had a significant 219 positive and linear relationship $(R_{marginal}^2=2.0\%)$ with the belief that a stimulus was real 220 $(\beta_{poly1}=16.57,\,95\%\ CI=[7.33,25.82],\,z=3.51,\,p<.001)$ for males, and a quadratic 221 relationship for females ($\beta_{poly2} = 7.82, 95\%$ CI = [1.81, 13.84], z = 2.55, p = .011), with both non-attractive and attractive faces being judged as more real. Attractiveness was also 223 found to have a significant positive and quadratic relationship with confidence in judging 224 faces both as real $(\beta_{poly2} = 4.30, 95\% \ CI = [0.97, 7.64], z = 2.53, p = .011)$ and as fake 225 $(\beta_{poly2} = 5.23, 95\% \ CI = [0.86, 9.60], z = 2.35, p = .019)$ for females. For males, however, a 226 significant negative and quadratic relationship was found between attractiveness ratings 227

and belief confidence only for faces judged as fake ($\beta_{poly2} = -9.92$,

95% CI = [-18.99, -0.86], z = -2.15, p = .032). There was no interaction with reported

self-attractiveness.

Beauty, adjusted for trustworthiness and familiarity, had a significant positive and linear relationship ($R_{marginal}^2 = 2.0\%$) with the belief that a stimulus was real ($\beta_{poly1} = 11.82, 95\%$ CI = [4.28, 20.21], z = 2.76, p = .006) for males only. No effect on confidence was found, aside from a quadratic relationship in females for faces judged as fake, suggesting that non-beautiful and highly beautiful faces were rated as fake with more confidence than average faces ($\beta_{poly2} = 7.84, 95\%$ CI = [3.39, 12.29], z = 3.46, p < .001). There was no interaction with reported self-attractiveness.

Trustworthiness, adjusted for beauty and familiarity, had a predominantly positive and linear relationship ($R_{marginal}^2 = 2.0\%$) with the belief that a stimulus was real ($\beta_{poly1} = 6.44, 95\%$ CI = [-0.11, 13.00], z = 1.93, p = .0054) for females only. No effect on confidence was found for males, whereas a quadratic relationship was found for females for both faces judged as real ($\beta_{poly2} = 6.14, 95\%$ CI = [2.13, 10.14], z = 3.00, p = .003) as well as fake ($\beta_{poly2} = 6.12, 95\%$ CI = [1.49, 10.75], z = 2.59, p = .001), suggesting that non-trustworthy and highly trustworthy faces were rated with more confidence than average faces.

We did not find any significant relationships for familiarity adjusted for beauty and trustworthiness ($R_{marginal}^2 = 2.0\%$). However, a significant positive and linear relationship was found between familiarity and the confidence judgements of rating faces as real ($\beta_{poly1} = 9.98, 95\%$ CI = [3.83, 16.13], z = 3.18, p = .001) whereas a negative linear relationship was found with those judged as fake ($\beta_{poly1} = -12.41$, 95% CI = [-20.27, -4.54], z = -3.09, p = .002) for males only. This hence suggests that males more confidently judge faces as real with when they are familiar, and as fake when they are unfamiliar.

Inter-Individual Correlates of Simulation Monitoring. The models including
the personality traits suggested that *Honesty-Humility* had a significant negative
relationship with the confidence associated with real as well as fake judgements
($\beta_{real} = -1.62, 95\% \ CI = [-2.55, -0.70], z = -3.43, p < .001; \beta_{fake} = -1.16,$ 95% CI = [-2.09, -0.23], z = -2.45, p = 0.014).

Significant positive associations were found between the probability of judging faces 259 as real and dimensions of narcissism such as Acclaim Seeking ($\beta = 2.24$, 260 95% $CI = [1.17, 4.27], z = 2.44, p = .015), and Manipulativeness (<math>\beta = 0.47,$ 261 95% CI = [0.25, 0.87], z = -2.4, p = 0.017). Confidence judgements also shared significant 262 links with narcissism through various facets, such as a positive relationship between the 263 confidence for both real and fake judgements with Acclaim Seeking ($\beta_{real} = 1.65$, 264 95% $CI = [0.59, 2.70], z = 3.07, p = .002; \beta_{fake} = 1.62, 95\% \ CI = [0.56, 2.68], z = 3.00, p = .002; \beta_{fake} = 1.62, p = .$ 265 p = .003), and a negative relationship with Authoritativeness ($\beta_{real} = -1.57$, 95% $CI = [-2.58, -0.57], z = -3.08, p = .002; \beta_{fake} = -1.49, 95\% CI = [-2.50, -0.48],$ z = -2.89, p = .004).

A positive trend was found in the relationship between the *Persecutory Ideation* dimension of paranoid thinking and the belief that the faces were real ($\beta = 1.87$, 95% CI = [0.99, 3.54], z = 1.93, p = .054).

The Prospective Anxiety aspect of intolerance to uncertainty shared a negative trend in its association with confidence ratings ($\beta_{real}=1.43,\,95\%$ $CI=[0.10,2.76],\,z=2.10,$ $p=.036;\,\beta_{fake}=-0.91,\,95\%$ $CI=[-1.93,0.11],\,z=-1.75,\,p=.081$). No significant effect was found for social anxiety.

Questions pertaining to the attitude towards AI were reduced to 3 dimensions
through factor analysis, labelled AI-Enthusiasm (loaded by items expressing interest and
excitement in AI development and applications), AI-Realness (loaded by items expressing

positive opinions on the ability of AI to create realistic material), and AI-Danger (loaded by items expressing concerns on the unethical misuse of AI technology). However, only AI-Enthusiasm displayed a significant positive relationship with the confidence in both real and fake judgements ($\beta_{real} = 0.21$, 95% CI = [0.02, 0.40], z = 2.20, p = .028; $\beta_{fake} = 0.31$, 95% CI = [0.12, 0.50], z = -8.90, p < 0.001).

284 Discussion

This study aimed at investigating the effect of facial ratings (attractiveness, beauty, 285 trustworthiness and familiarity) on simulation monitoring, i.e., on the belief that a stimulus 286 was artificially generated. Most strikingly, despite all the stimuli being real faces from the 287 same database, all participants believed (to high degrees of confidence) that a significant 288 proportion of them were fake. This finding not only attests to the effectiveness of our 289 instructions, but highlights the current levels of expectation regarding CGI technology. 290 The strong impact of prior expectations and information on reality beliefs demonstrated 291 here underlines the volatility of our sense of reality. In fact, stimuli-related and 292 participant-related characteristics accounted together for less than 20% of the beliefs 293 variance, suggesting a large contribution of other subjective processes. 294

Although attractiveness did not seem to be the primary drive underlying simulation 295 monitoring of face images, we do nonetheless report significant associations, with a different 296 pattern observed depending on the participant's gender. The quadratic relationship found 297 for female participants is aligned with our hypothesis that salient faces (i.e., rated as very 298 attractive or very unattractive) are judged to be more real. The fact that this effect did not reach significance for beauty underlines that attractiveness judgement, and its role in simulation monitoring, is a multidimensional construct that cannot be reduced to physical 301 facial attractiveness, in particular for women (Buunk et al., 2002; Qi & Ying, 2022). In 302 fact, female participants were more confident in judging faces as fake only when they were 303 rated very high or low on beauty, suggesting that physical beauty and attractiveness are 304

not analogous in their effects on simulation monitoring decisions.

Interestingly, we found a significant positive linear relationship in male participants 306 for both attractiveness and beauty on simulation monitoring that we could interpret under 307 an evolutionary lens. Specifically, males purportedly place more emphasis on facial 308 attractiveness as a sign of reproductive potential, as compared with females, who tend to value characteristics signaling resource acquisition capabilities (Buunk et al., 2002; Fink et 310 al., 2006; Qi & Ying, 2022). It is thus possible that the evolutionary weight associated with 311 attractiveness skewed the perceived saliency of men towards attractive faces, rendering 312 them significantly more salient than unattractive faces, and in turn distorted the relationship with simulation monitoring. However, future studies should test this saliency-based hypothesis by measuring constructs closer to salience and its effects, for 315 instance using neuroimaging (Indovina & Macaluso, 2007; Lou et al., 2015) or physiological 316 markers (e.g., heart rate deceleration, Skora et al., 2022). 317

Our results found a positive linear trend between trustworthiness and simulation 318 monitoring for females only. Given prior evidence that faces presented as 319 computer-generated were rated less trustworthy (Balas & Pacella, 2017; Hoogers, 2021; 320 Liefooghe et al., 2022), we expected such a linear association to be more clearly present for 321 both genders. One of the underlying mechanisms that possibly contributed to this 322 dimorphism could be the increased risk-taking aversion reported in females (explained 323 evolutionarily as a compromise to their reproductive potential, Van Den Akker et al., 324 2020), to which perceived facial trustworthiness relates (Hou & Liu, 2019). However, if that was the case, faces judged as highly untrustworthy should have appeared as even more salient (representing an evolutionary threat), and hence be judged as more real, leading to a quadratic relationship between trustworthiness and simulation monitoring instead. 328 Further studies are needed to investigate the causes of the increased simulation monitoring 320 sensitivity to trustworthiness in females. 330

Contrary to our hypothesis, we did not find familiarity to be significantly related to 331 simulation monitoring decisions. Interestingly, there were significant linear relationships 332 between familiarity and confidence judgements for males only, where familiarity increased 333 the confidence of reality beliefs. Although the familiarity measure was not a "recognition" 334 measure, evidence from studies pertaining to the latter could be linked, reporting better 335 face memory for females (Lewin & Herlitz, 2002; Mishra et al., 2019; Sommer et al., 2013), 336 as well as an overconfidence in face recall for males (Bailey, 2021; Herbst, 2020). However, 337 it should be noted that the present study's distribution of familiarity ratings was strongly 338 skewed, and only a low number of pictures was rated as highly familiar. As such, future 339 studies should clarify this point by experimentally manipulating familiarity, for instance by 340 modulating the amount of exposure to items before querying the simulation monitoring 341 judgements.

Regarding the role of inter-individual characteristics in simulation monitoring 343 tendencies, we found higher scores of honesty-humility - a trait related to an increased risk 344 perception and aversion (Levidi et al., 2022; Weller & Thulin, 2012) - to be related to a 345 lower confidence in simulation monitoring judgements. Notably, greater narcissistic 346 tendencies in dimensions such as acclaim seeking and manipulativeness were associated 347 with a higher number of faces judged as real. This is in line with recent research which 348 found people with narcissism to be less likely to engage in analytical reasoning strategies 340 such as reflective thinking (Ahadzadeh et al., 2021; Littrell et al., 2020), and to be more 350 vigilant and attentive to external stimuli (Carolan, 2017; Eddy, 2021; Grapsas et al., 2020). 351

Moreover, putting the significant positive links between narcissistic acclaim seeking
and confidence judgements in perspective with the negative correlation between
honesty-humility and narcissism (Hodson et al., 2018), we confirm previous evidence
regarding the relationship between narcissistic grandiosity and over-confidence in
decision-making (Brunell & Buelow, 2017; Campbell et al., 2004; Chatterjee & Pollock,

2017; O'Reilly & Hall, 2021). Although an inverse effect was found for the narcissistic facet
of authoritativeness, we interpret this relationship as related to a higher response
assertiveness. Taken together, these results suggest that participants with low humility and
high recognition desires are more confident in their judgement regarding the real or fake
nature of ambiguous stimuli. Alternatively, participants with opposite traits might perceive
a higher risk in the decision-making process and its potential consequences (e.g., being seen
as bad at the task at hand), resulting in more conservative confidence ratings.

Our findings suggest - though with weak significance - a positive link between
paranoid ideation and the tendency to believe that the stimuli were real. Given previous
reports that people with higher levels of paranoia are more sensitive to cues of social threat
(Fornells-Ambrojo et al., 2015; Freeman et al., 2003; King & Dudley, 2017), it is plausible
that paranoid traits confer greater saliency and emotionality to observed faces, hence
increasing perceptions of its realness. This hypothesis, if confirmed by future studies, would
be in line with previous findings that persecutory delusions are predicted by a greater sense
of presence in VR environments populated with virtual characters (Freeman et al., 2005).

Despite the ubiquity of AI, the literature pertaining to the influence of people's AI 372 attitudes on simulation monitoring is scarce. Contrary to our expectations, we did not find 373 evidence for the role of participants' expectations regarding the capabilities of AI 374 technology (in terms of the realism of its productions). Instead, we found only one's 375 enthusiasm about AI technology to be related to an increased confidence in simulation 376 monitoring ratings. This could potentially be because participants with a highly positive attitude towards AI perceive themselves as having greater knowledge about AI and its 378 capabilities (Said et al., 2022), hence permitting themselves to be more confident in their 379 simulation monitoring decisions. In fact, this result is in line with reports that AI attitudes 380 interacts with people's perceived self-knowledge to influence their perception of the 381 opportunities and risks accorded by AI applications (Said et al., 2022). 382

On a methodological level, although the order of presentation of the facial images was 383 randomized to reduce effects of adaptation, participants were more confident in their 384 judgements for faces perceived as real following a shorter re-exposure delay. Such shorter 385 durations could be associated with the faces being better remembered and appearing more 386 familiar, thereby triggering self-referential and autobiographical memory processing during 387 the repeated display (Abraham & Von Cramon, 2009; Gobbini et al., 2013; Taylor et al., 388 2009). Indeed, this finding is consistent with studies in which fictional stimuli that were 380 associated with familiarity up-regulated emotions, biasing its salience and perceived 390 realness (Makowski et al., 2017; Sperduti et al., 2016). However, if that was the case, we 391 would expect shorter re-exposure delays to impact the decision bias as well towards reality, 392 rather than simply the confidence. Future studies should further investigate the 393 modulatory effects of types and degrees of familiarity on perceived realness judgements.

Several limitations have to be noted. The current experimental paradigm required 395 participants to judge the realness of faces they had prior exposure to (which was done to 396 prevent reality judgements from influencing the other ratings). Although the effect of 397 re-exposure delay was negligible, the potential bias induced by face familiarity (as 398 compared to judging completely new items) cannot be discarded. Future studies could 399 examine that by incorporating novel face images or increasing the duration of the 400 re-exposure delay. Moreover, the magnitude of the effects found in the study was relatively 401 small, suggesting that the facial features measured in the study were not the key 402 determinants of simulation monitoring. Hence, beyond exploring new potential 403 mechanisms, future studies should include a more thorough debriefing to try to capture 404 what conscious strategies (if any) the participants used (e.g., focusing on some features of 405 the stimulus - like hair or eyes in the case of faces) to guide their reality beliefs.

In summary, the aim of the present study was to examine whether a subset of specific characteristics, in particular face attractiveness, significantly influences our simulation

monitoring decisions. Notably, we found faces rated as attractive to be perceived as more
real, with a possible sexual dimorphism affecting the shape of the relationship. We also
found that inter-individual traits, such as narcissistic acclaim-seeking and
manipulativeness, as well as persecutory ideation, were related to a systematic bias towards
beliefs that the stimuli were real or fake. We hope subsequent works to further our
understanding of the factors driving the reality beliefs pertaining to ambiguous stimuli, an
question becoming increasingly pertinent given the rapid technological advances.
